

1.What is GraphQL?

GraphQL is a query language for APIs and a runtime for executing those queries. It allows clients to request exactly the data they need.

2. What problems GraphQL is trying to solve?

GraphQL reduces over-fetching (receiving unnecessary data) and under-fetching (needing additional requests for missing data). It also allows different clients to request different combinations of fields from the same API.

3. How to use GraphQL?

The server defines a schema describing the available data and implements resolvers to fetch or modify it. Clients send queries to read data and mutations to change data, specifying which fields they want returned.

4. What are the differences between REST and GraphQL?

REST typically uses multiple resource endpoints and HTTP methods such as GET and POST, with predefined response structures. GraphQL typically uses one endpoint, with queries and mutations, and lets clients select response fields. GraphQL can fetch related data in one request, but requires more careful handling of query performance, caching, and authorization.
